The **Z**-content of products generated in **reactions catalyzed** by adamantyl-activated **Z**-selective metathesis **catalysts** is at first very high but degrades at higher conversions. The degree to which this undesirable **process** occurs is dependent on both the substrate and **catalyst** structure. Studies of **Z-to-E isomerization processes** and **methods** of preventing them are explored. Furthermore, an interesting Fischer carbene species was found to affect these **isomerization processes**.
